

### Solutions to Sample Assignment A

- 1(a)** What is the most general form of a strategy for this game? For each input received (0 or 1), there can be some probability distribution for the resulting guess. However, in the case of input 1 guessing I is *never* correct. Therefore, no generality is lost if we restrict our attention to strategies of this form (for some parameter  $\epsilon \in [0, 1]$ ):

Strategy B( $\epsilon$ )

if the bit received is 0 then randomly guess  $\begin{cases} \text{I} & \text{with probability } 1 - \epsilon \\ \text{II} & \text{with probability } \epsilon \end{cases}$   
 if the bit received is 1 then guess II

(Any strategy that is not of this form can be improved by changing it to always guess II in the case of input 1.)

For set-up I, this strategy succeeds with probability  $1 - \epsilon$ . For set-up II, this strategy succeeds with probability  $\frac{1}{2} + \frac{1}{2}\epsilon$ . Therefore, the average-case success probability of strategy B( $\epsilon$ ) is the average of these two success probabilities

$$\frac{1}{2}(1 - \epsilon) + \frac{1}{2}\left(\frac{1}{2} + \frac{1}{2}\epsilon\right) = \frac{3}{4} - \frac{1}{2}\epsilon + \frac{1}{4}\epsilon \quad (1)$$

$$= \frac{3}{4} - \frac{1}{4}\epsilon. \quad (2)$$

This is maximized when  $\epsilon = 0$ . Therefore, strategy B(0), which is the same as strategy A, achieves optimum average-case success probability.

Note: In the context of *average-case* success probability, we need only consider the four deterministic strategies and check that strategy A is the best among these. This is a consequence of a general result that's sometimes referred to as "Yao's Lemma". A solution along these lines would need to include a clear statement or reference to that lemma (omitted here). It should be noted that there is no such lemma for *worst-case* success probability; in fact, in part (b) the optimal strategy is *not* deterministic.

- 1(b)** The highest possible worst-case success probability is  $\frac{2}{3}$  (higher than what strategy A attains). To see why this is so, we refer to the strategies of the form B( $\epsilon$ ) that we defined in part (a) (without loss of generality, we need only consider strategies of the form B( $\epsilon$ )). The worst-case success probability of B( $\epsilon$ ) is the minimum of the success probabilities of the two cases, which is

$$\min \left\{ 1 - \epsilon, \frac{1}{2} + \frac{1}{2}\epsilon \right\}. \quad (3)$$

For what value of parameter  $\epsilon$  is this maximized? Since  $1 - \epsilon$  decreases as a function of  $\epsilon$  and  $\frac{1}{2} + \frac{1}{2}\epsilon$  increases as a function of  $\epsilon$ , the expression is maximized at the value of  $\epsilon$  where the expressions are equal

$$1 - \epsilon = \frac{1}{2} + \frac{1}{2}\epsilon, \quad (4)$$

which occurs when  $\epsilon = \frac{1}{3}$ . Therefore, worst-case success probability is maximized by strategy B( $\frac{1}{3}$ ) and is  $\frac{2}{3}$ .

2. If the rotation  $R_\theta$  is applied then the two states become

$$R_\theta|0\rangle = \cos(\theta)|0\rangle + \sin(\theta)|1\rangle \quad \text{vs.} \quad R_\theta|+\rangle = \cos(\theta + \frac{\pi}{4})|0\rangle + \sin(\theta + \frac{\pi}{4})|1\rangle. \quad (5)$$

Since  $\theta \in [0, \pi/4]$ ,  $R_\theta|0\rangle$  is closer to  $|0\rangle$  than  $|1\rangle$ , and  $R_\theta|+\rangle$  is closer to  $|1\rangle$  than  $|0\rangle$ . Therefore, we can assume that: for measurement outcome 0 the guess is 0; and for outcome 1 the guess is + (i.e., it's easy to check that guessing + in case of outcome 0 would lead to a lower success probability).

The average-case success probability as a function of  $\theta$  is

$$p(\theta) = \frac{1}{2}|\langle 0|R_\theta|0\rangle|^2 + \frac{1}{2}|\langle 1|R_\theta|+\rangle|^2 = \frac{1}{2}\cos^2(\theta) + \frac{1}{2}\sin^2(\theta + \frac{\pi}{4}). \quad (6)$$

For what  $\theta \in [0, \pi/4]$  is this maximized? Since  $p(\theta)$  is differentiable, we can use calculus to determine where the maximum is. The derivative is

$$p'(\theta) = -\cos(\theta)\sin(\theta) + \sin(\theta + \frac{\pi}{4})\cos(\theta + \frac{\pi}{4}) \quad (7)$$

$$= -\frac{1}{2}\sin(2\theta) + \frac{1}{2}\sin(2(\theta + \frac{\pi}{4})), \quad (8)$$

where we have used the formula  $\sin(2x) = 2\sin(x)\cos(x)$  in Eq. (8).

The derivative is zero when

$$\sin(2\theta) = \sin(2(\theta + \frac{\pi}{4})). \quad (9)$$

Since  $\theta = \theta + \frac{\pi}{4}$  cannot occur, the only way for Eq. (9) to be satisfied is if

$$2(\theta + \frac{\pi}{4}) = \pi - 2\theta \quad (10)$$

(using the fact that  $\sin(x) = \sin(\pi - x)$ ). This occurs if and only if  $\theta = \pi/8$ . Therefore the optimal rotation angle  $\theta \in [0, \frac{\pi}{4}]$  must be one of  $0, \frac{\pi}{8}, \frac{\pi}{4}$ . It's easy to check these three cases and  $\theta = \frac{\pi}{8}$  is the optimum. For  $\theta = \frac{\pi}{8}$ , the average-case success probability is

$$p(\frac{\pi}{8}) = \frac{1}{2}\cos^2(\frac{\pi}{8}) + \frac{1}{2}\sin^2(\frac{\pi}{8} + \frac{\pi}{4}) \quad (11)$$

$$= \cos^2(\frac{\pi}{8}). \quad (12)$$

---

Note: For this state distinguishing problem,  $\cos^2(\frac{\pi}{8})$  is also the highest worst-case success probability.

3. Suppose that

$$\begin{aligned} \frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|11\rangle &= (\alpha_0|0\rangle + \alpha_1|1\rangle)(\beta_0|0\rangle + \beta_1|1\rangle) \\ &= \alpha_0\beta_0|00\rangle + \alpha_0\beta_1|01\rangle + \alpha_1\beta_0|10\rangle + \alpha_1\beta_1|11\rangle. \end{aligned} \quad (13)$$

We'll show that this results in a contradiction. Eq. (13) implies

$$\alpha_0\beta_0 = \frac{1}{\sqrt{2}} \quad (14)$$

$$\alpha_0\beta_1 = 0 \quad (15)$$

$$\alpha_1\beta_0 = 0 \quad (16)$$

$$\alpha_1\beta_1 = \frac{1}{\sqrt{2}}. \quad (17)$$

There is no solution to these equations because Eq. (15) implies that either  $\alpha_0 = 0$  (which contradicts Eq. (14)) or  $\beta_1 = 0$  (which contradicts Eq. (17)).
